Abstract

The exposure to tobacco smoke could cause bronchoconstriction and acute asthma attack. Smoking asthmatics have an insufficient therapeutic response to the standard therapy and unsatisfactory improvement of the respiratory function.

In a randomized parallel study, a therapeutic response to inhaled fluticasone propionate in a dose of 250 µg twice per day was determined in 38 asthmatics with mild asthma, smokers and nonsmokers. Short-acting ß2 agonist (salbutamol) in a dosage of 0.1 mg/per inhaled dose was used as a rescue medication when needed. In patients, asthma was detected with a positive metacholine test and/or positive bronchodilatator response of > 12% with ≥ 200 ml increase of FEV1. They were randomized in two groups according to sex, age and starting values of FEV1. Before and after 6 weeks of treatment with fluticasone propionate of the previously corticosteroid-naive patients, lung function test (spirometry) was performed.

A statistically significant effect (p<0.05) was achieved during the fluticasone propionate therapy in a group of non-smoking asthmatic patients. The same effect was not seen in the group of smoking asthmatics. Although the percentage of elevated FEV1 values was small, it was satisfactory because of the starting FEV1 values in patients with mild asthma.

More studies are needed in asthmatics determining the asthma symptom score, the number of night awakenings due to asthma, the asthma exacerbations and the frequency of rescue therapy usage which will define the altered therapeutic response to inhaled corticosteroids in smoking asthmatics.

Keywords: asthma, spirometry, inhaled corticosteroids

Introduction

According to the World Health Organization in 2015, there were 1.1 billion smokers in the world, and although it has been a declining habit worldwide, the prevalence is increasing in the Eastern Mediterranean region and Africa.

* arso66@yahoo.com
the developed countries approximately 17-35% from the asthmatics are smokers (Thomson et al., 2004).

The following factors contribute towards reduced respiratory function among active smokers with asthma: the number of smoked cigarettes, the presence of wheezing, low body mass, a low forced expiratory volume in 1 second (FEV1) or a low ratio between FEV1 and FVC where FVC represents forced vital capacity, additional professional exposition and air pollution. Also, smokers with asthma had also reduced compliance (i.e. the patients were not using the prescribed drugs because of the feeling that they did not have any effect). Apostol et al. in 2002 conducted a research with 4000 adults from 18 to 40 years old, evaluating the decline of FEV1 over a ten year period. It has been established that among non-smokers without asthma the annual decline in FEV1 was 8.5%, among non-smokers with asthma 10.1%, among smokers without asthma 11.1% and the highest decline of FEV1 was detected among smokers with asthma: 17.8%. Faster decrease of FEV1 in asthmatic smokers compared to asthmatics who do not smoke has also been detected in other studies (Tamimi et al., 2012; Viegi et al. 2003). However, among smokers with asthma that stopped smoking, after the first week, a statistically significant increase in FEV1 was noticed (Chaudhuri et al., 2006). In ex-smokers and non-smokers with asthma, Thompson and Spears found improvement of FEV1 and asthma control (Thomson and Spears, 2005). Tonnesen and his coworkers (Tonnesen et al., 2007), also found that if the patient had stopped smoking, the rate of decline of FEV1 significantly decreased similar to a non-smoker. However, despite a possible increase of FEV1 after smoking cessation, FEV1 would never reach the values of a non-smoker.

According to Chalmers and his coworkers (Chalmers et al., 2001) asthmatic smokers have an increased number of cells in the bronchoalveolar lavage, in which neutrophils are more prevalent, in contrast to non-smoking asthmatics; while the number of eosinophils has a decrease in percentage among asthmatic smokers compared to asthmatic non-smokers. The guidelines for treatment of bronchial asthma recommend the inhaled steroids as the most effective anti-inflammatory treatment of asthma (National Heart, Lung and Blood Institute and world Health Organization. National Asthma Education Program, 1997; BTS/SIGN,2003). It was shown that the inhaled steroids reduce the symptoms and the exacerbations and they improve the respiratory function (Barns and Ulrik 2015; Barnes et al., 1998). They lead to a reduction of the risk for death from asthma (Barnes et al., 1998; Lanes et al., 2002).

The aim of the study was to evaluate the altered therapeutic response to the recommended average therapeutic doses of fluticasone propionate on the respiratory function among smokers with mild asthma. Objectives of the study were to determine the difference between FEV1 before and after inhaled corticosteroid treatment in smokers and nonsmokers with mild asthma.

Material

In a randomized, parallel study an investigation was done with 38 asthmatics with mild asthma. Among patients, within the age group of 18-50 years asthma was detected with previously positive dose-provoking methacholine test and/or a positive bronchodilator response from >12% with ≥200ml increase in FEV1. The age of the patients included was limited to 50 years, in order to avoid the inclusion of patients with COPD. Because of the same reasons, patients that smoke more than 40 cigarettes per day or patients that have been smoking more than 15 years have not been included.

The patients were randomized in two groups, according to gender, age and starting FEV1, group of smokers and non-smokers, among which the therapeutic response to inhaled fluticasone propionate was determined. Considered for non-smokers were persons who have never smoked, or have been smoking only for two years during their whole life, or stopped smoking at least one year before the examination. Considered for smokers were those who smoke 10-40 cigarettes per day or had a smoking history of 2 to 15 years, but without diagnosis of COPD.

Design of the study

At the beginning of the research, demographic information, information regarding the beginning and duration of the asthma, symptoms of the disease, past diseases, family, social and pharmacological anamnesis were obtained from the history of the patient. All patients who smoked were advised to stop smoking, but those who refused were included in the study as asthmatic smokers. During the study, the condition of the patients was followed by outpatient monitoring.

In all patients, previously untreated with inhaled corticosteroids, the spirometric tests were made by using a Power-Cube spirometer. Tests were done before and after 6 weeks of treatment with fluticasone propionate. Patients were treated according to the criteria and recommendations of the Global Initiative for Asthma (GINA) and according to adopted national programs for the treatment of asthma in the Republic of Macedonia (Global Initiative for Asthma, GINA, 2017).

The therapeutic response to inhaled fluticasone propionate, measured by FEV1 was determined among patients at a dose of 250μg twice a day (total daily dose of 500μg). As a facilitator drug, a short-acting β2 agonist – bronchodilator, salbutamol from 0.1mg, per inhaled dose, was used if needed. FEV1 was expressed in percentage from the predicted normal value for each person according to race, gender, age, height and weight.

For statistical analysis descriptive methods, a method with mean value, standard deviation, Mann Whitney test and confidence interval of 95% (p<0.05) were used.
Results

Pulmonary function was analyzed in a group of 38 patients with mild asthma, 16 smokers and 22 non-smokers (Fig. 1).

Fig. 1. Smokers and non-smokers with asthma.

There is no significant difference obtained between the two groups according to the age and the values for FEV1 before the beginning of the examination (Table 1; Fig. 2).

There is no statistically important difference between the values for FEV1 before the beginning of the examination (Table 2; Fig. 3).

After six weeks of treatment with inhaled fluticasone propionate with a dose of 250mg twice per day (a total daily dose of 500 mg), a statistically significant positive effect for FEV1 (p<0.05) was obtained from the therapy with fluticasone propionate among the group of asthmatic non-smokers compared to the effect of the therapy for the group of asthmatic smokers (Table 3; Fig. 4). Although the values of FEV1 given in percentage of improvement are small, they are satisfactory for initial spirometric values of patients with mild asthma.

As in our survey, the perceived reduced benefit of corticosteroid therapy among the asthmatics exposed to cigarette smoke due to reduced sensitivity has also been demonstrated in several other studies, starting in 1996 by Pedersen and his coworkers (Pedersen et al., 1996). They found out that within 3 months of treatment with inhaled corticosteroid (ICS) – budesonide at a dose of 1600 mg per day, there was an excellent response among non-smoking asthmatics, with statistically significant increase of FEV1, but this effect was completely absent among the asthmatic smokers, treated with the same product during the same period of time. Tomlison and coworkers (Tomlinson et al., 2005) during a 12 week survey, demonstrated that up to 2000 mg per day of inhaled (inhalation) beclomethasone was necessary among asthmatic smokers in order to achieve some positive effect on the peak expiratory flow – PEF, but even that effect was much smaller from the achieved effect with only 400 mg per day beclomethasone among non-smokers with asthma. There was a similar unwanted and inappropriate response obtained in a treatment with fluticasone propionate at a dose of 1000 mg per day. Even the use of oral prednisolone did not give the desired effects among asthmatic smokers. Furthermore, two other randomized controlled studies among smokers with asthma, proved that the effectiveness of the therapy is disrupted after a short period of treatment with inhaled or oral corticosteroids (Chalmers et al., 2002; Chaudhuri et al., 2003).

the asthmatic smokers compared to the asthmatic non-smokers, despite the several weeks of treatment.

The test for determination of the lung function (FEV1) had worse results among asthmatic smokers.

There was an altered therapeutic response towards inhaled corticosteroids in average doses which it was not sufficiently expressed among asthmatics who smoke.

Among smokers with asthma, other treatment modalities are needed, like increasing the dose of inhaled corticosteroids, use of combined bronchodilator/corticosteroid therapy and/or adding low doses of aminophylline.

![Fig. 4. FEV1 values after 6 weeks of therapy with fluticasone propionate.](image)

According to Chauduri and his coworkers (Chauduri et al., 2006), managing asthma among smokers should result in encouragement to quit smoking, early initiation of increased use of inhaled corticosteroids, use of a combined therapy, use of antagonists of leukotriene receptors or providing high doses of inhaled steroids and/or oral steroid therapy. The author gives these recommendations based on the fact that quitting smoking improves the lung function (improved values of FEV1 before the inhalation of salbutamol, as well as persistence of the positive effect after 1, 3 and 6 weeks). During a course of oral prednisolone, there was an increase of 15% in FEV1 after 6 weeks and an increase of 22% in FVC (850 ml). It should be emphasized that the experimental group was treated with medium sized doses of inhaled corticosteroid.

In smokers with asthma, new effective therapies that are being investigated are: anti IL8, anti IL 1β, anti TNFa, NF κB inhibitors, PDE4 inhibitors, LTB4 inhibitors, development of improved inhalers, more secure steroids with higher doses and/or therapy with IFNα (Global Initiative for Asthma, GINA, 2017, Braganza et al., 2008; Barns 2003). In the treatment of the asthmatics that smoke, a creation of new drugs which will ease smoking cessation, as well as vaccines, is expected.

### Conclusions

This survey verifies the assumption that the therapeutic response towards inhaled corticosteroids is reduced among the asthmatic smokers compared to the asthmatic non-smokers, despite the several weeks of treatment.

The test for determination of the lung function (FEV1) had worse results among asthmatic smokers.

There was an altered therapeutic response towards inhaled corticosteroids in average doses which it was not sufficiently expressed among asthmatics who smoke.

Among smokers with asthma, other treatment modalities are needed, like increasing the dose of inhaled corticosteroids, use of combined bronchodilator/corticosteroid therapy and/or adding low doses of aminophylline.
